## Abstract

The transition from fossil fuels to clean energy requires a large-scale shift in technological development from fossil to clean technologies. We analyze how a major negative shock to the expected income of oil producers may contribute to a shift among the suppliers to the oil industry from dirty to clean R&D. First, we develop a theoretical framework of directed technical change, where we show that a negative shock to the income of firms producing a dirty final good may induce these firms' suppliers to shift their R&D activity towards clean innovation. Second, we exploit a major oil price shock in 2014 and propose a novel method of identifying firms' exposure to variations in the oil price. We find that firms that were relatively more exposed to the oil price shock, through the supply chain of oil producers, increased their clean R&D investments more than firms that were less exposed to the shock. Our findings have important implications for how to design effective policies that promote environmentally sustainable economic growth.

JEL codes: D25, F61, O31, O44, Q55.

Keywords: Directed technical change, clean innovation, firm dynamics.

# 1 Introduction

The transition away from a fossil-energy based economy has become an imperative in the face of mounting environmental challenges and increasing global demand for sustainable development (Stern (2007); Stiglitz et al., 2009). Technological change is going to be a key to reaching these ambitious targets. Understanding the drivers of green technological change is therefore vital to understand the overall effectiveness of different climate policy measures.

In this paper we investigate how firms that supply inputs to producers of dirty final goods, react to a strong negative price shock to the dirty final goods by switching their resources from dirty to clean R&D activities. After peaking at \$108 a barrel on June 20, 2014, the oil price plunged to \$44 a barrel by January 28, 2015, a drop of 60 percent in a little over 7 months. This was a large, negative, and exogenous shock to the current and future price of oil and the shock provides a natural experiment to study the dynamics of resource reallocation within firms that supply the oil industry.

We first develop a theoretical framework which builds on the model of directed technical change in Acemoglu et al. (2012). We consider an economy where two goods, clean and dirty, are produced by combining a range of inputs. Technological progress is driven by investment in innovation by the firms producing inputs. We extend the model by Acemoglu et al. by two additional key features. First, we assume that rescaling of the stock of R&D personnel is associated with an adjustment cost for the firm. <sup>1</sup> This extension of the model implies that in the aftermath of a negative shock to expected returns to dirty innovation, firms with pre-existing capabilities in dirty innovation will face an incentive to divert their R&D activities towards clean innovation. Second, we allow for spillovers from the more mature, dirty, R&D activity towards clean R&D. This extension works in the opposite direction: After a negative shock to dirty innovation returns, exposed firms will scale down all types of R&D.

The theoretical model allows us to develop a set of propositions which we take to the data. Our empirical analysis is based on detailed micro data from Norway, a country which has a major oil extraction industry and a large fringe of firms supplying inputs to this industry. We start by documenting a few stylized facts which motivate our analysis. First, we show that there is persistence in R&D activities at the firm level: a firm that has positive R&D expenditures in one period has a 90 percent probability of continuing in the subsequent period. Second, we find that the share of firms with clean R&D increases sharply around the time of the shock. Third, we show that the majority of the increase in

---

<sup>1</sup>We build on the framework in Bloom et al. (2013), which is motivated by the empirical finding that firms facing increased low-cost competition in international markets increase their innovation efforts, see Bloom et al. (2012).

clean R&D is coming from firms that have on-going investments in non-clean R&D. These facts indicate that the negative shock to expected profits in the oil supply industry had implications for clean R&D in the sector, but also that existing firms reacted differently to the shock.

We estimate the causal effect of the oil price shock on clean R&D investments in firms supplying inputs to oil producing firms. We propose a novel method for identification where we rely on firm-level trade data to compute a measure of firm exposure to the oil price shock. We find that firms that are more exposed to the 2014 fall in oil prices increase their clean R&D more than firms that are less exposed to the shock. This is true if we look at the likelihood of investing in clean R&D, the share of clean relative to non-clean R&D, or the value of clean R&D. We also document that the firms which are most exposed to the shock have higher probabilities both of starting new investments in clean R&D, and of switching from non-clean to clean R&D. In light of our theoretical model, we argue that our findings suggest that there are within-firm adjustment costs for R&D.

Digging further into the mechanisms, we investigate whether the firms we identify as being more exposed to the negative oil price shock experience subsequent decreases in sales and profits. This is indeed the case, as sales per employee decreases, as does profits, although the latter finding is not as robust as the first. We also explore whether the exposed firms simply intensify their R&D investments across the board, but this is not the case. We find no effect on total R&D investments, the number of R&D employees or on the share of R&D employees in total employment.

Our empirical findings support the hypothesis that within-firm dynamics lead firms already engaged in dirty innovation to redirect their innovation efforts towards clean technologies as a response to a negative shock to future profits in fossil energy production and extraction.

The paper relates to several strands of literature. The theoretical framework builds directly on the well-established literature on directed technical change and climate, in particular Acemoglu et al. (2012).<sup>2</sup> Dechezleprêtre and Hémous (2022) provide a recent review.<sup>3</sup> We add to this literature by including within-firm dynamics, in a model allow-

---

<sup>2</sup>This newer literature itself builds on seminal papers on directed technical change, such as Hicks (1932) and Acemoglu (2002).

<sup>3</sup>Acemoglu et al. (2012) underline the key role of R&D subsidies in climate policy, in addition to a carbon price, when there is path dependency in technical change. Acemoglu et al. (2016) estimate a similar model using micro data from US energy markets and conclude that, although the carbon tax plays an important role, subsidies for clean R&D are key to achieving the shift from dirty to clean technologies. Similar conclusions are drawn in Greaker et al. (2018). The key role of R&D subsidies in optimal climate policy is also underlined by Casey (2024). Hart (2019) use a model structure closer to that normally used in integrated assessment models of climate change (see e.g. Golosov et al. (2014)), resulting in a more important role for the carbon price. By allowing for complementarities between technology and energy inputs in production, Lemoine (2024) reaches a similar conclusion with regards to the importance

ing for innovation to take place both in clean and dirty technology at the same time. Our paper shares the feature of parallel innovation in both sectors with Fried (2018), who presents a dynamic general equilibrium model with endogenous innovation, which is calibrated using historical oil shocks. Our paper complements Fried’s in several ways. First, by offering a well-identified empirical exploration of the effect of a negative shock to the expected future profits from oil extraction, and, second, by highlighting a specific channel through which clean R&D is affected by the shock from the supply-side, through within-firm dynamics.

On the empirical side, the paper contributes to the literature investigating the relation between relative energy prices and clean innovation. The findings of Newell et al. (1999) indicate that higher energy prices will induce more rapid development of energy-saving technologies. Similarly, Popp (2002) finds that higher energy prices are associated with a significant increase in energy-saving innovations at the industry-level. Aghion et al. (2016), who made another key contribution to this literature, showed that firms in the auto industry tend to innovate more in clean and less in dirty technologies when they face higher tax-inclusive fuel prices. A similar pattern, with a positive relationship between energy prices and energy-saving innovation are also found by Crabb and Johnson (2010), Cabel and Dechezleprêtre (2016), Ley et al. (2016) and Hu et al. (2023).<sup>4</sup> Popp (2002) underlines the useful distinction between demand and supply side factors driving technical change. The main focus of this literature has been the demand-side effect on clean innovation of changes in relative energy prices: As prices of fossil fuels rise, incentives for clean innovation are strengthened. We focus on a specific channel through which lower prices to producers of fossil energy can speed up clean R&D efforts from the supply side. Specifically, we show that our empirical findings are in line with within-firm costs of rescaling R&D activity. We also study a wide range of firms and we have rich information about the firms and do not have to rely on patent data to measure clean innovation.<sup>5</sup>

Lastly, the paper speaks to the new and active literature on shock propagation in networks. Barrot and Sauvagnat (2016) identify firm-specific shocks among supplier firms, and find that their domestic buyers experience substantial losses as a consequence. Dhyne et al. (2022) focus on the opposite direction and examine how suppliers are affected when their buyers are hit by shocks. Most of this literature is focused on short-run effects

---

of sufficient carbon pricing.

<sup>4</sup>See also Dugoua and Gerarden (2023) and Dugoua and Dumas (2021) for recent contributions to the literature on environmental policy and energy prices. See Popp et al. (2010) and Popp (2019) for reviews of the literature on environmental policy and innovation more broadly.

<sup>5</sup>See Golosov et al. (2014) for a key contribution to the literature on optimal carbon pricing, and Timilsina (2022) and Köppl and Schratzenstaller (2023) for reviews of this literature. Important contributions to the broader literature on optimal climate policy are, among others, Gerlagh et al. (2009), Stern and Valero (2021) and Blanchard et al. (2023).

of short-run shocks; we contribute by focusing on a large and persistent shock and its effect on investments.

The paper is organized as follows. Section 2 lays out the theoretical model of directed technical change with within-firm transition costs and technology spillovers. In Section 3, we describe the context and data used for the empirical analysis, and present a set of stylized facts. The empirical strategy is described in Section 4, while the empirical results are presented in Section 5. In Section 6 we provide some concluding remarks.

## 2 Theoretical Framework: Directed Technical Change with Adjustment Costs and Technological Spillovers

In this section, we develop a stylized model of directed technical change, to guide our empirical analysis on the impact of a permanent drop in the price of fossil fuels on investments in clean R&D. We build on Acemoglu et al. (2012), and develop a model that allows us to investigate how a negative price shock to a dirty final good may propagate through the supply chain and induce a diversion of R&D investments from dirty to clean R&D among input producers. In particular, our model allows us to illustrate how clean R&D activity in firms supplying inputs to the fossil energy extraction sector may react differently to a drop in the oil price, compared to firms that do not deliver their inputs to the fossil fuel producers.

We extend the model by Acemoglu et al. (2012) by allowing firms to differ in their innovation productivity with respect to dirty and clean R&D. The heterogeneity across firms implies that firms make different choices regarding clean and dirty R&D activity. Moreover, we build on the empirical findings of for example Bloom (2007) who finds that R&D investments are highly persistent across business cycles, and attribute this finding to adjustment costs of rescaling activity. To reflect such adjustment costs, we include a convex cost of rescaling the size of the R&D activity within the firm. Finally, we assume that there are within-firm spillovers from the more mature R&D activity (dirty) to the less mature (clean) activity.

### 2.1 The Model

Consider a discrete-time, infinite-horizon economy where two final goods,  $j = c, d$ , are produced in each time period. The clean good, denoted by subscript  $c$ , in quantity  $Y_{ct}$ , and the dirty good, denoted by subscript  $d$ , in quantity  $Y_{dt}$ . We consider a small, open economy and therefore the final-good prices are exogenously given.

Each final good is produced by competitive producers using a continuum of inputs

that are specific to the type of final good produced, with the production technology:

$$Y_{jt} = \int_0^1 A_{jit}^{1-\alpha} x_{jit}^\alpha di, j = c, d, \quad (1)$$

with  $\alpha \in (0, 1)$  where  $x_{jit}$  is the quantity of input  $ji$ .  $A_{jit}$  denotes the productivity of the input. We abstract away from the use of other inputs such as labor in the final good sector, in order to keep the framework as simple as possible.

There is a mass of 1 firms that can produce inputs. The unit cost in production of inputs is constant and independent of both type and productivity of the input, given by  $\phi$ . Without loss of generality, we follow Acemoglu et al. (2012) and let  $\phi = \alpha^2$ .

Innovation takes place within the input-producing firms. Define  $A_{jt}$  as the aggregate state of the technology for the final good type  $j$  at time  $t$  across all firms producing inputs, with:

$$A_{jt} \equiv \int_0^1 A_{jit} di. \quad (2)$$

A successful innovation for input  $x_{jit}$  will increase the productivity of the input,  $A_{jit}$ , by a common factor  $(1 + \gamma) > 1$ . Let subscript  $k$  denote a firm  $k$ . When an innovation for input  $ji$  happens in firm  $k$ , the firm obtains a one-period patent and is allocated the monopoly rights for input  $x_{ji}$  for the current time period. We follow Acemoglu et al. (2012) and assume that for all inputs with no successful innovation, the monopoly rights are allocated to a random firm.

To innovate, the firms must hire scientists to conduct R&D activity. There is a mass of 1 scientists available in the market, and they have skills that can be used for both clean and dirty R&D. A firm hiring a scientist chooses whether to put a scientist to work on dirty or clean R&D. A scientist that is hired for type- $j$  R&D activity is randomly assigned to an input of that type. The input producers act competitively in the market for scientists. Let  $s_{kjt}$  be the number of scientists hired by firm  $k$  for type- $j$  R&D activity in period  $t$ , and let  $s_{kt} = s_{kdt} + s_{kct}$ , be the total number of scientists hired by firm  $k$  in period  $t$ .

Firms are heterogenous and the probability of innovation of type  $j$  in firm  $k$  depends on a firm and final good specific innovation productivity,  $\eta_{kj} \in \{0, \eta_j\}$  with  $\eta_j \in (0, 1)$ , and on a concave innovation production function  $g^j(\cdot)$ . We allow for within-firm technological spillovers from the more mature (dirty) R&D activity towards the less mature (clean) R&D activity. For the relevant range of  $s_{kct}$  and  $s_{kdt}$ , the clean-innovation production function is therefore given by  $g^c(s_{kct}, s_{kdt})$ , with  $g^c(0, s_{kdt}) = 0$ ,  $g^c(1, 1) \leq 1$ ,  $\partial g^c / \partial s_{kct} > \partial g^c / \partial s_{kdt} \geq 0$ ,  $\partial^2 g^c / \partial s_{kct}^2 < 0$ ,  $\partial^2 g^c / \partial s_{kdt}^2 = 0$  and  $\partial^2 g^c / \partial s_{kct} \partial s_{kdt} \geq 0$ , while all third derivatives are zero.

For dirty innovation, only the number of scientists working on dirty R&D is relevant, since there are no technological spillovers from the less mature towards the more mature R&D activity. The dirty-innovation production function is given by  $g^d(s_{kdt})$ , with  $g^d(0) = 0$ ,  $g^{d'}(\cdot) > 0$ ,  $g^{d''} < 0$ ,  $g^{d'''} = 0$  and  $g^d(1) \leq 1$ .<sup>6</sup>

Firms will not engage in R&D of type  $j$  if their innovation productivity for that type is zero. We can therefore divide the input producers into four groups, depending on  $\eta_{kc}$  and  $\eta_{kd}$ :

- Group *I*:  $\eta_{kc} = \eta_c$ ,  $\eta_{kd} = 0$ . Engage only in clean R&D.
- Group *II*:  $\eta_{kc} = 0$ ,  $\eta_{kd} = \eta_d$ . Engage only in dirty R&D.
- Group *III*:  $\eta_{kc} = \eta_c$ ,  $\eta_{kd} = \eta_d$ . Engage in both types of R&D.
- Group *IV*:  $\eta_{kc} = 0$ ,  $\eta_{kd} = 0$ . Are not active (can be disregarded).

Let  $\lambda^l \in [0, 1]$  denote the share of firms that belong to group  $l$ , with  $\lambda^I + \lambda^{II} + \lambda^{III} + \lambda^{IV} = 1$ .

We further assume that the rescaling of R&D activity is subject to adjustment costs. To reflect such adjustment costs we include a convex cost of rescaling the size of the R&D activity within the firm.<sup>7</sup> To keep the framework as simple as possible, the adjustment cost is separable from the innovation productivity and given by:

$$R_k = c \cdot \left( \frac{s_{kt} - s_{kt-1}}{s_{kt-1}} \right)^2, \quad (3)$$

for firm  $k$ , with  $c > 0$ . Note that a key to the results presented in the following is that the cost of rescaling depends on the overall level of R&D activity in the firm, not on whether the activity is related to clean or dirty inputs.

The aggregate productivity of type- $j$  inputs will develop over time according to:

$$A_{ct} = \left( 1 + \gamma \int_0^1 \eta_{kc} g^c(s_{kct}, s_{kdt}) dk \right) A_{ct-1} \quad (4)$$

$$A_{dt} = \left( 1 + \gamma \int_0^1 \eta_{kd} g^d(s_{kdt}) dk \right) A_{dt-1} \quad (5)$$

with  $\int_0^1 s_{kt} = 1$  in equilibrium. Allocation of scientists is therefore, of course, drives the technological state of the economy in the long run. In the following, we make one further simplifying assumption, namely that all input producers are myopic in the sense

---

<sup>6</sup>To ensure an interior solution with respect to  $s_{kjt}$  to the problem of a firm with  $\eta_{kj} = \eta_j$ , we assume  $\lim_{s_{kdt} \rightarrow 0} g^d(s_{kdt}) = \infty$  and  $\lim_{s_{kct} \rightarrow 0} g^c(s_{kct}, s_{kdt}) = \infty$ .

<sup>7</sup>The assumption of convex adjustment costs is standard in the labor market literature, see e.g. Hamermesh (1995)

that they do not take future adjustment costs into account when they make their R&D investment decision. <sup>8</sup>The value of potential innovation as a result of investment in R&D arise in the current time period, and are of course included in the firms' objectives.

## 2.2 Market Equilibrium

Let  $p_{jt}$  denote the exogenous price of final good  $j$  in period  $t$ , while  $p_{jit}$  denotes the price of input  $ji$ . The producer of final good type  $j$  will choose inputs to maximize profits:

$$\max_{x_{jit}} p_{jt} \int_0^1 A_{jit}^{1-\alpha} x_{jit}^\alpha di - \int_0^1 p_{jit} x_{jit} di. \quad (6)$$

Solving the maximization problem gives the downward-sloping demand for each input:

$$p_{jit}(x_{jit}) = \alpha p_{jt} A_{jit}^{1-\alpha} x_{jit}^{\alpha-1}. \quad (7)$$

The monopolistic producer of good  $x_{jit}$  will maximize profits subject to the final good producers' demand for inputs. In equilibrium, production of, and profits related to, input  $ji$  are given by

$$x_{jit} = A_{jit} p_{jt}^{\frac{1}{1-\alpha}} \quad (8)$$

$$\pi_{jit} = \alpha(1 - \alpha) A_{jit} p_{jt}^{\frac{1}{1-\alpha}} \quad (9)$$

The expected within-period revenue from hiring a scientist for type- $j$  R&D activity for firm  $k$  in period  $t$ , denoted  $I_{kjt}$ , is given by:

$$I_{kct} = \eta_{kc} g^c(s_{kct}, s_{kdt}) \int_0^1 \pi_{cit} di = \eta_{kc} g^c(s_{kct}, s_{kdt}) \alpha(1 - \alpha) p_{ct}^{\frac{1}{1-\alpha}} (1 + \gamma) A_{ct-1} \quad (10)$$

$$I_{kdt} = \eta_{kd} g^d(s_{kdt}) \int_0^1 \pi_{dit} di = \eta_{kd} g^d(s_{kdt}) \alpha(1 - \alpha) p_{dt}^{\frac{1}{1-\alpha}} (1 + \gamma) A_{dt-1} \quad (11)$$

Because scientists are randomly assigned to a variety within the type they are hired for, it is the aggregate input quality for that type,  $A_{jt-1}$ , that determines the expected revenue from hiring.

Scientists are paid wage  $w_t$ , and firm  $k$  thus hires scientists to solve the following

---

<sup>8</sup>Forward-looking firms will take into account not only the current adjustment costs, but also those expected to be incurred in the future. For a firm adjusting its R&D up or down, the expected future adjustment costs provide an incentive to rescale somewhat quicker, relative to the optimal rescaling for a myopic firm. However, as long as the future adjustment costs are discounted, the key effect of including the adjustment costs on the firms' decisions is captured in the myopic problem presented in the following. Hence, we make the assumption about myopic behaviour in order to keep the framework as simple as possible.

problem in period  $t$ :

$$\max_{s_{kdt}, s_{kct}} \left\{ \alpha(1 - \alpha)(1 + \gamma) \left( \eta_{kc} p_{ct}^{\frac{1}{1-\alpha}} A_{ct-1} g^c(s_{kct}, s_{kdt}) + \eta_{kd} p_{dt}^{\frac{1}{1-\alpha}} A_{dt-1} g^d(s_{kdt}) \right) - w_t s_{kt} - c \cdot \left( \frac{s_{kt} - s_{kt-1}}{s_{kt-1}} \right)^2 \right\}, \quad (12)$$

subject to  $s_{kt} = s_{kct} + s_{kdt}$ .

We let the resulting demand for scientists from a firm  $k$  in group  $I$ , which only conducts clean R&D activity, be given by  $s_{kct}^I(p_{ct}, w_t)$ . Demand for scientists from firm  $k$  in group  $II$ , which only conducts dirty R&D activity, is given by  $s_{kdt}^{II}(p_{dt}, w_t)$ , and demand for scientists from firm  $k$  in group  $III$ , which conducts both types of R&D activity, is given by  $s_{kct}^{III}(p_{ct}, p_{dt}, w_t)$  and  $s_{kdt}^{III}(p_{ct}, p_{dt}, w_t)$ . The fourth group of firms does not conduct any research and does therefore not demand any scientists. Equilibrium in the market for scientists requires that the demand for scientists in each period  $t$  from each group of input producers is equal to the supply of scientists, which we have set to one:

$$\lambda^I s_{kct}^I(p_{ct}, w_t) + \lambda^{II} s_{kdt}^{II}(p_{dt}, w_t) + \lambda^{III} s_{kct}^{III}(p_{ct}, p_{dt}, w_t) + \lambda^{III} s_{kdt}^{III}(p_{ct}, p_{dt}, w_t) = 1 \quad (13)$$

We note that group  $I$  is not directly affected by a change in the price of dirty goods, while group  $II$  is not directly affected by a change in the price of clean goods.

## 2.3 Comparative Statics

Let us now consider the effect of a fall in the price of the dirty final good on clean innovation. Specifically, we want to compare the effect for a firm in group  $III$ , that is engaged in both clean and dirty R&D, to that of a firm in group  $I$ , that is only engaged in clean R&D. Because we want to compare otherwise similar firms, assume now that all firms have the same total number of scientists hired in the previous period, i.e.  $s_{kt-1} = s_{t-1}$  for all  $k$ . To get at these effects, we must consider all general-equilibrium effects in the model.

We show in the Appendix Section ?? that the direct effect of a fall in the price of the dirty final good on demand for scientists is negative for firms in group  $II$  and  $III$ , which supply the producers of the dirty final good with inputs: Their revenue falls, and returns to dirty R&D innovation fall. As a consequence, these firms will reduce their dirty R&D activity and thus their demand for scientists, which in turn leads to a decline in wages (see equations 29, 32 and 37).

The decline in wages will induce all firms that are active in R&D, including the firms in group  $I$ , to expand their R&D activity (see equations 33-36).

Firms in group *III* are active in both dirty and clean R&D. The impact of a price shock for dirty goods on their clean R&D activities depends both on the wage effect, which is also experienced by firms in group *I*, as well on within-firm dynamics related to technological spillovers and adjustment costs: The presence of technological spillovers implies that reduced dirty R&D activity leads to lower marginal productivity of scientists working on clean innovation,. This in turn leads to reduced clean R&D activity. Adjustment costs, on the other hand, imply that these firms increase the resources they allocate towards clean innovation, relative to firms in group *I*, because the net marginal cost of their clean R&D activity decreases as they downscale their dirty R&D. In other words, the adjustment costs make firms shift some of their scientist from dirty to clean R&D rather than firing them. The effect of a change in the price of the dirty final good on the demand for scientists for clean R&D activity in group *III* depends on what effects that dominate.

The following two propositions summarize our key conclusions regarding the relative impact of a price shock for firms that only conduct clean R&D (group *I*) and firms active in both clean and dirty R&D (group *III*), using the case without spillovers and adjustment costs as a benchmark:

**Proposition 1.** *When there are no within-firm technological spillovers, and there are no adjustment costs, a drop in the price of the dirty final good,  $p_{dt}$ , will induce the same change in clean R&D in all firms engaged in clean R&D, independently of whether the firms are also active in dirty R&D or not:*

$$\frac{ds_{kct}^I}{dp_{dt}} = \frac{ds_{kct}^{III}}{dp_{dt}}. \quad (14)$$

*Proof.* All calculations and expressions are provided in the Appendix, Section B, see specifically Equation 41. When  $\partial g^c / \partial s_{kdt} = \partial^2 g^c / \partial s_{kct} \partial s_{kdt} = c = 0$ , it follows

that the direct effect on clean R&D, the first term in Equation 39, is zero for firms in both groups. Moreover, the indirect effect (the second term in Equation 39 and the full expression in Equation 40) is the same across the two groups.  $\square$

**Proposition 2.** *If there are within-firm technological spillovers and adjustment costs, and the effect of the adjustment costs dominates the spillover effect, firms engaged in both dirty and clean R&D will respond to a fall in the price of the dirty final good by increasing their clean R&D activity, compared to the firms only engaged in clean R&D:*

$$\frac{ds_{kct}^{III}}{dp_{dt}} > \frac{ds_{kct}^I}{dp_{dt}}. \quad (15)$$

*If, on the other hand, the spillover effect dominates the effect of the adjustment costs,*

*the firms with both dirty and clean R&D activity, will respond to the price fall by reducing their clean R&D activity relative to the firms only engaged in clean R&D activity:*

$$\frac{ds_{kct}^{III}}{dp_{dt}} < \frac{ds_{kct}^I}{dp_{dt}}. \quad (16)$$

*Proof.* See the Appendix, Section B, specifically Equation 41. □

### 3 Data and Stylized Facts

In this section, we first present the large, negative shock to oil prices that occurred in the second half of 2014, which we shall use to identify the consequences of a big drop in the price of a dirty final good for investments in clean R&D. We then present the rich data at hand, and document three stylized facts, which together with the theoretical framework presented above, motivate our empirical design.

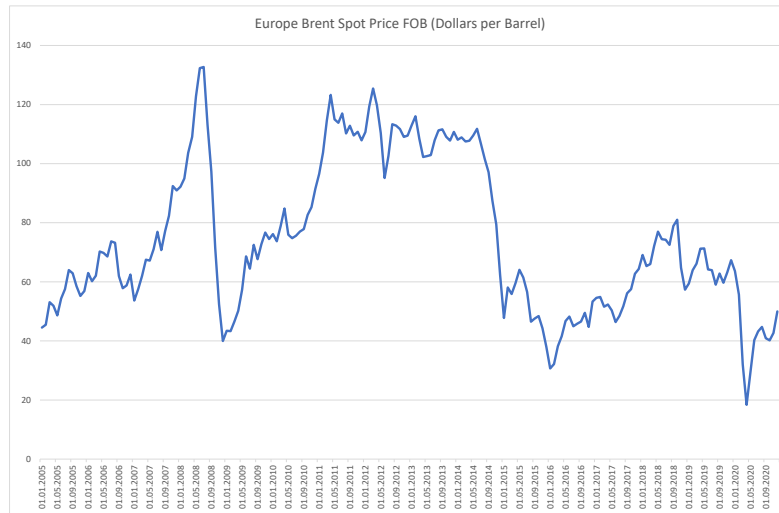

#### 3.1 The oil shock

Our analysis relies on a quasi-natural experiment created by the large and sudden drop in oil prices. After peaking at \$107.95 a barrel on June 20 2014, the oil price plunged to \$44.08 a barrel by January 28, 2015, a drop of 59.2 percent in a little over 7 months. The oil price plunged in 2014 due to a set of factors. The main reason was a combination of an oversupply in the market and low global demand for oil. The increased production of shale oil in the US increased substantially, while the OPEC countries contributed to the oversupply by maintaining high production levels despite the falling price. At the same time, the economic slowdown in China and Europe reduced the global demand for oil, further exacerbating the supply-demand imbalance.

The result was a large, negative shock to the current and future price of oil. Figure 1 shows the development of the price of Brent oil over the time period we study. As can be clearly seen from the graph, oil prices plummeted starting in June 2014. Figure 2 shows the future price of oil as estimated in Q4 of 2014, and clearly illustrates that markets anticipated that prices would remain low for the foreseeable future. This drop in future prices is important for our analysis, as the decisions firms are making about investments in R&D are forward-looking in nature, and firms are unlikely to respond much to temporary fluctuations in the price. For individual firms in the supply chain, such as the firms we include in our analysis in this paper, the price fall must be treated as exogenous. Hence, the 2014 oil price drop serves an ideal quasi-natural experiment that allows us to study the dynamics of resource reallocation among firms that supply

the oil extraction industry.

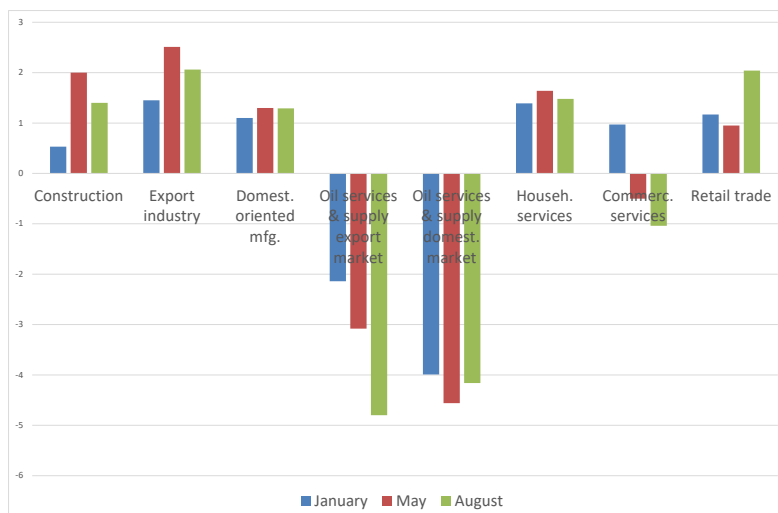

Figure 2: Crude Oil Price and Oil Future Prices

Note: The figure plots the Crude Oil Price until end 2014 and Oil Future Prices from 2015 to 2017. Source: The Norwegian Central Bank Monetary Policy Report 4/2014.

The fall in the oil price in 2014 had a substantial negative impact on expected output growth in the firms in Norway supplying the oil industry. Figure 3 reports the results from the business sector survey conducted regularly by the Norwegian Central bank for the period January to August 2015. According to the survey, expectations varied significantly across sectors, with a positive outlook in most sectors, while the industries serving and supplying the oil sector stand out, with a very negative outlook for both domestic sales and exports. It should be noted that the technology, intermediates and capital goods used for offshore extraction of oil differs substantially from the technology used for onshore oil extraction. It is therefore unlikely that the firms supplying the Norwegian offshore industry experienced increased demand for their product as a consequence of the positive shale oil shock in the US.

Figure 3: Expected Output Growth

Note: The figure shows expected annual output growth the coming six months by sector in the Norwegian economy based on the Norwegian Central bank regular survey of the business sector. Source: The Norwegian Central Bank Monetary Policy Report 3/2015.

### 3.2 Data

Our empirical analysis is based on five data sets. The first data set is administrative firm register data from Statistics Norway. The data set covers the universe of firms across all sectors. The firm register provides information on the date of the entry and exit of each individual firm, allowing us to calculate the firm's age. The register also holds data on firms' number of employees.

The second data set is income statement and balance sheet data from Statistics Norway for all private non-financial joint-stock companies. Since 85 percent of Norwegian firms with one or more employees are joint-stock firms, this means that it covers almost the entire universe of firms in Norway. The income statement and balance sheet data are based on data from annual accounting reports that, according to Norwegian law, must be filed with the public Register of Company Accounts.

The third data set is the R&D survey. The survey provides information about the value of R&D expenditures, the number of and the wage bill of R&D personnel. Importantly, the survey also gives information about the share of R&D related to clean energy. More detailed descriptions of the R&D data can be found in the Appendix ,Section A.

The fourth data set is product-level trade data for the universe of firms in Norway. The data is at the HS8 product-level and covers all goods that are imported or exported by Norwegian firms.

The fifth data set provides complete information on all direct support from the government for R&D and innovation to firms.<sup>9</sup> We link all data sets with a unique firm identifier.

### 3.3 Sample selection

For our analysis, we focus on all joint stock firms in the manufacturing sector (NACE #10 to 35) that are covered by the R&D survey. This gives us an unbalanced panel of approximately 1,300 firms per year. We focus on the manufacturing sector, as these firms are responsible for the vast majority of trade in goods. We use information about which goods are imported by oil producers (NACE 06) to construct our exposure measure as described below in Section 4.1. Our sample is constructed to cover the years 2007 to 2017. The years 2007-2013 define the pre-shock period, and 2014-2017 define the post-shock period.

### 3.4 Stylized facts on R&D and clean R&D

We present three stylized facts on the development of R&D and clean R&D in the aftermath of the oil price shock.

*Fact 1: There is persistence in R&D activities at the firm-level.* A firm that has positive R&D expenditures in one period, has a 90 percent probability of continuing in the subsequent period. This inertia in R&D activities is in line with the empirical findings of Bloom (2007) who finds that R&D investments are highly persistent across

---

<sup>9</sup>For more details see <https://www.ssb.no/en/teknologi-og-innovasjon/forskning-og-innovasjon-i-naeringslivet/statistikk/naeringspolitiske-virkemidler>.

business cycles, and supports the hypothesis that the rescaling of R&D activity is subject to adjustment costs.

Table 1: Annual transition rates

Status year t	Status year t+1	
	No R&D	R&D
No R&D	0.862	0.138
R&D	0.098	0.902

Note: The table shows transition rates for firms in the baseline sample and covers the years 2007 to 2017.

*Fact 2: The share of firms investing in clean R&D increased after the oil price shock both in absolute and relative terms.* In 2013, the share of firms with positive R&D in our sample was 40 percent and the share of firms investing in clean R&D was only 5 percent. Fast-forward to 2017, and the numbers have increased to 46 percent for overall R&D, whereas the share of firms investing in clean R&D has more than doubled, to 11 percent. Figure 4 shows the increase in the share of firms with clean R&D expenditure relative to all firms engaged in R&D firms.

Figure 4: Share of firms with clean R&D

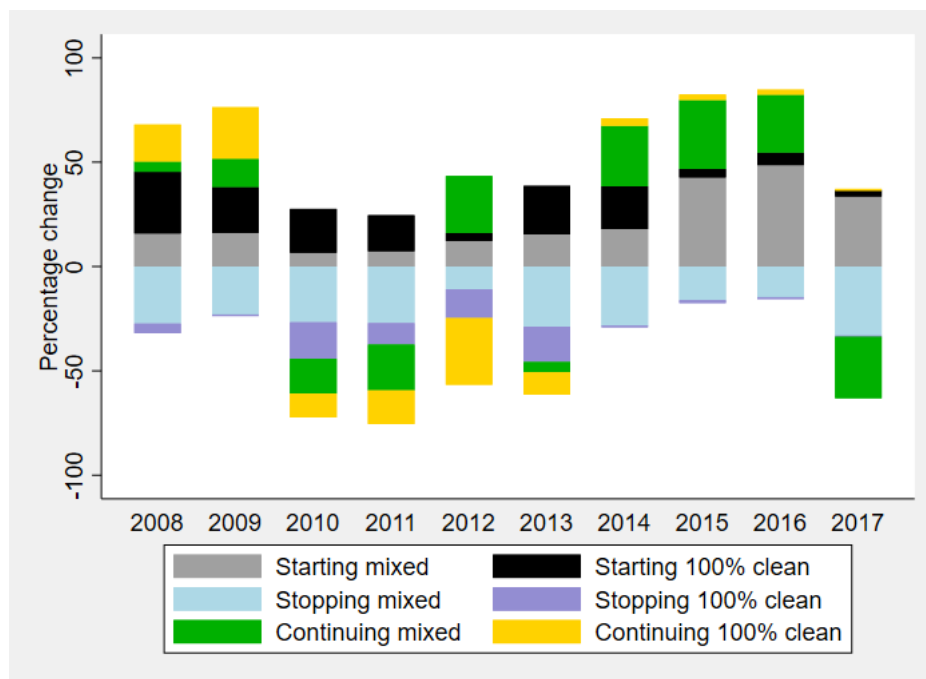

Note: The table shows the share of firms in the baseline sample that reports investments in clean R&D. The sample covers the years 2007 to 2017.

*Fact 3: The majority of the increase in clean R&D comes from firms that have ongoing investments in non-clean R&D.* Figure 5 shows how the aggregate change in clean R&D can be decomposed into 3 categories: firms starting to do R&D (including new

entrants), firms who stop doing R&D (including exiting firms), and continuing R&D performers. For each of these categories, we split firms into two groups, depending on whether their R&D investments are 100 percent clean or a combination of clean and non-clean. As the graph shows, the majority of the increase in clean R&D after the oil price shock comes from firms with both clean and non-clean R&D.

Figure 5: Decomposition of Clean R&D

Note: The figure shows the annual percentage change in clean R&D – decomposed according to the status of the firm, i.e. whether the firm starts, stops or continues investment in both clean and dirty R&D (“mixed”), or starts, stops or continues investment in just clean R&D. The sample covers the years 2007 to 2017.

## 4 Empirical Strategy

The point of departure for our empirical analysis is the theoretical framework developed above. According to Proposition 2, the relative impact of an oil price shock on exposed firms (group *III*) relative to non-exposed firms (group *I*) is ambiguous. It thus remains an empirical question. To investigate this question we develop a novel measure of identification which makes us able to rely on firms’ heterogeneous exposure to the shock in our analysis.

## 4.1 Identification: Measuring the exposure to the shock

To make progress towards estimating the causal effects of the oil price shock, we need to identify which firms are exposed to the shock. The standard approach in the literature has been to rely on sectoral input-output tables, which provide the share of production in an industry  $i$  that is bought by industry  $j$ . However, this would not be satisfactory for our purposes for two main reasons.

First, we are interested in the firm-level reaction to the shock, and we know from a large literature in international trade that firms are very heterogeneous even within narrowly defined industries. As we will describe below, our exposure measure shows that there is a lot of variation in actual treatment within industries that would be classified as either treated or control if we rely on sectoral input-output tables.

Second, if our treatment were defined at the industry-level, we would not be able to control for any other contemporaneous shocks to industries.

Therefore, we instead develop a novel firm-specific exposure measure leveraging the detailed trade data. We exploit the rich information we have about firm-level imports by oil producers to identify which products they use in their production, and construct our firm-specific exposure measure by following these steps:

1. Identify the HS8 products imported by the oil producing industry (NACE #6) in the pre-shock period. (2007-2013)<sup>10</sup>
2. Identify the firms in manufacturing that export products that are imported by the oil producing industry ( $j \in o$ ).
3. Calculate firm-level exposure  $x_{ok}$  as the share of “oil products” in firms’ total export basket in 2013 as  $x_{ok} = \sum_{j \in o} x_{kjt} / \sum_j x_{kjt}$  for  $t = 2013$ .

More details on the construction and underlying assumptions are given in the Appendix, Section C.

Measuring exposure to the shock in this way has some clear advantages compared to using sector-level input-output tables. First, it captures the fact that the oil price shock was a global shock. Compared to measuring the exposure only through domestic linkages, we are capturing the extent to which firms are exposed to the oil price drop through international trade. Second, and crucial for identification, it gives firm-level variation in exposure. Compared to using sectoral input-output linkages, using our exposure measure allows us to control for other, potentially time-varying, factors that are affecting all firms in an industry.

---

<sup>10</sup>We use a period of more than one year, to account for the fact that firms’ sourcing of capital goods we be subject to lumpiness over time.

Using our exposure measure does come at a cost, as it reduces the sample to only goods-exporting firms in the manufacturing sectors, and we are therefore not able to capture firms that trade in services. Moreover, our measure relies on the assumption that a firm's share of exports directed towards the oil producing industry is an appropriate measure of the share of the firm's activity devoted to these products.

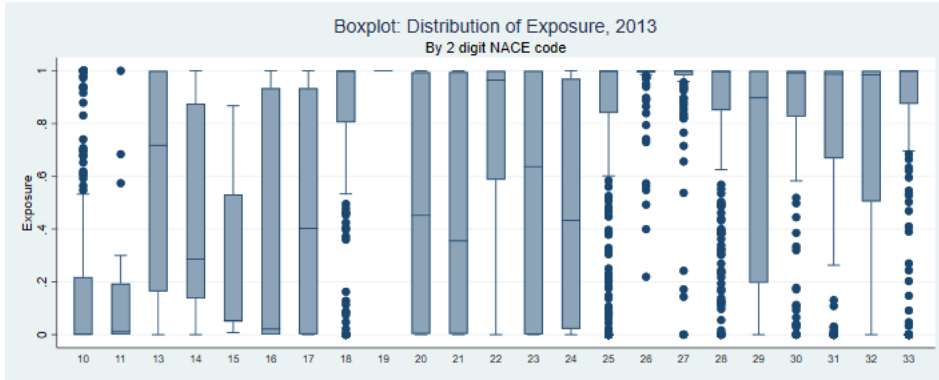

Figure 6 highlights the importance of using a firm-specific measure. The box plot describes the within-industry variation in the exposure measure for all of our manufacturing industries. The median of the exposure measure is shown by the line within the box, and the box's boundaries represent the first (Q1) and third (Q3) quartiles, indicating the middle 50 percent of the data. The difference between Q3 and Q1 is the interquartile range (IQR), and the whiskers extend from the box to the smallest and largest values within 1.5 times the IQR from the quartiles, highlighting the range of the data. The points outside this range are plotted individually as outliers, indicating data points that differ significantly from the rest of the distribution.

The box plot shows that there is substantial variation in the exposure of firms within practically all of the manufacturing industries. An alternative to our approach would be to follow the commonly used classification from Statistics Norway, which defines sectors with at least 50 percent of its value of production directed to the petroleum sector to be oil related.<sup>11</sup> This would in practice mean that we would have classified all firms in industries 25, 26, 27, 28, 30 and 33 as being affected by the shock, and firms in all other industries as not affected. We find it reassuring that these sectors also stand out as being strongly affected with our approach. However, as Figure 6 shows, there is substantial exposure also among firms in the other industries. In particular, NACE 22 (Manufacture of rubber and plastic products), NACE 29 (Manufacture of motor vehicles, trailers and semi-trailers), NACE 31 (Manufacture of furniture) and NACE 32 (Other manufacturing) stand out as having medians close to 1.

Figure 6: Within-industry Variation in Exposure

Note: The median of the exposure measure is shown by the line within the box, and the box’s boundaries represent the first (Q1) and third (Q3) quartiles, indicating the middle 50 percent of the data. The difference between Q3 and Q1 is the interquartile range (IQR), and the whiskers extend from the box to the smallest and largest values within 1.5 times the IQR from the quartiles. The points outside this range are plotted individually as outliers.

## 4.2 Empirical Model

To estimate the effects of the oil price shock, we rely on a difference-in-difference model based on the theoretical framework developed in Section 2. This model allows us to causally identify the effect of the oil price shock on clean R&D investments, as we compare firms that are more affected by the oil price shock to other firms – before and after 2014. The baseline specification takes the form:

$$y_{kt} = \alpha_k + \beta x_{ok} \times Post_t + \gamma Z_{kt} + \delta_{st} + \varepsilon_{kt}, \quad (17)$$

where the outcome variable  $y_{kt}$  are various measures related to clean R&D investments.  $x_{ok}$  depicts firm exposure to the shock based on the product portfolio (see Section 4.1), while  $\alpha_k$  are firm fixed effects, capturing all time-invariant differences between the more exposed and less exposed firms. Crucially, we are able to control for industry-year fixed effects (NACE 2-digit). These industry-specific trends are captured by  $\delta_{st}$ . Our coefficient of interest is  $\beta$ , which captures how firms exposed to the shock respond in the years following the shock.  $x_{ok}$  measures firm  $k$ ’s exposure as defined in Subsection 4.1 above, and  $Post_t$  is a dummy variable that equals one in the the post-period ( $t > 2013$ ).  $Z_{kt}$  is a vector of firm-level controls aimed at ensuring that the more exposed and less exposed firms are comparable. We include the following firm-level controls: log employment, log tangible assets, export share, and energy share, and a dummy which depicts whether or not the firm has received public funding for R&D and innovation. Energy share is calculated as energy cost related to production and transport relative to sum of opera-

tional costs.<sup>12</sup> As all of these variables themselves are possibly affected by the oil price shock, we measure them at baseline and interact with year dummies. Standard errors are clustered at the firm-level. On the left hand side, we include various measures of the firms' clean innovation activities, measures of income and profits, as well as measures of R&D activities more generally.

## 5 Empirical Results on Clean Innovation

Our main variables of interest are related to clean R&D activities. We start by analyzing the effect on the probability of doing clean R&D as measured by a dummy variable that takes the value of 1 if the firm reports any clean R&D investment, and 0 otherwise. The results from estimating different versions of Equation (17) with and without controls and fixed effects can be found in Table 2.

In column (1), we simplify and only include industry-year fixed effects. We find that for a firm with average exposure, the shock leads to an increase in the likelihood of reporting any clean R&D investment by approximately 4.5 percentage points relative to the firms in the control group, that are not exposed according to our measure. The baseline likelihood of having any clean R&D investment is 7.5 percent, meaning that this effect is substantial and of economic importance. In column (2), we add firm fixed effects, which attenuates the coefficient slightly, but not by much. In column (3), we add our baseline control variables, except that we leave out the control for the firm's energy share in the production process. We add this control in column (4) to reach our preferred specification. We find that the energy share is the only control variable that seems to have some bite. An effect of including energy share in the regression is not surprising, as firms with substantial use of energy in production may clearly also be affected by the oil price drop through this direct channel. We also estimate our preferred specification using PPML instead of OLS. Our results suggest that firms that were relatively more exposed to the oil price shock, due to their delivery of inputs to the oil producing sector, were more likely to invest in clean R&D after the shock.

---

<sup>12</sup>Manufacturing firms in Norway typically rely on two main sources energy: fossil fuels for transport and some types of machinery and electricity based on hydro power. In the Appendix Section D we show how firms' cost of energy have developed over time for each of these energy goods and in aggregate, see Figure 8.

Table 2: Probability of Clean R&amp;D

Variable:	Dummy (1)	Dummy (2)	Dummy (3)	Dummy (4)	Dummy (2)
$Post_t * x_{ok}$	0.044** (0.019)	0.039** (0.020)	0.042** (0.020)	0.055*** (0.020)	0.499** (0.199)
Controls ex. energy	No	No	Yes	Yes	Yes
Controls incl. energy	No	No	No	Yes	Yes
Firm FE	No	Yes	Yes	Yes	Yes
Industry*year FE	Yes	Yes	Yes	Yes	Yes
Estimator	OLS	OLS	OLS	OLS	PPML
Obs.	11,695	11,695	11,695	11,695	3,024

Note: Standard errors in parenthesis are clustered on firm. Controls include baseline levels of log employment, log tangible assets, export share, and a dummy for public funding, all interacted with year dummies. A control for energy share is included where indicated. \* $p < 0.1$ , \*\* $p < 0.05$ , \*\*\* $p < 0.01$ .

We are interested not only in the likelihood of investing in clean R&D, but also in the share of clean R&D in each firm's total R&D. To get at the share, we replace the dummy variable with a variable capturing the value of clean R&D investments relative to the total R&D investments of the firm. The results can be found in columns (1) and (2) in Table 3 below, and show a positive and significant effect also on this measure, although it is not as precisely estimated as the dummy. These findings suggest that firms exposed to the oil price shock are increasing their clean R&D investments relative to their non-clean investments relatively more than other firms. In columns (3) and (4) we replace the share of clean R&D with the value of clean R&D, in logs in column (3) and levels in column (4). Here, we find support for the hypothesis that exposed firms are increasing their clean R&D spending also in absolute terms, although the effect in column (4) is just below the threshold for significance at the 10 percent level.

Table 3: Clean R&amp;D: Share and Value

Variable:	Share (1)	Share (2)	Log Value (3)	Value (4)
$Post_t * x_{oi}$	1.575* (0.899)	0.358* (0.218)	0.346** (0.140)	0.716 (0.470)
Controls	Yes	Yes	Yes	Yes
Firm FE	Yes	Yes	Yes	Yes
Ind.*year FE	Yes	Yes	Yes	Yes
Estimator	OLS	PPML	OLS	PPML
Obs.	11,695	3,024	11,695	3,024

Note: Standard errors in parenthesis are clustered on firm. Log Value is measured as  $\log(1 + \text{Clean R\&D expenditures})$ . Controls include baseline levels of log employment, log tangible assets, export share, energy share and a dummy for public funding, all interacted with year dummies.  $*p < 0.1$ ,  $**p < 0.05$ ,  $***p < 0.01$ .

The findings presented in Table 2 and 3 support the hypothesis that firms exposed to the oil price shock through the oil producers' supply chain will react relatively stronger to the price shock, in terms of investments in green R&D.

We investigate further where the increase in clean R&D investments is originating – is it mainly due to firms that have previously not invested in any R&D that start investing, or is it mainly driven by firms with pre-existing R&D investments that reallocate their R&D spending towards clean activities? To get at this, we create two dummy variables: First, “New Clean” equals one if the firm reports spending on clean R&D in period  $t$  but did not in period  $t - 1$ . Second, “R&D to Clean” equals one if the firm reports spending on clean R&D in period  $t$  but did not in period  $t - 1$ , conditional on the firm reporting positive R&D spending in general in period  $t - 1$ .

The results from this exercise is found in Table 4. In column (1), we see a strong and positive coefficient, indicating that firms that are more exposed to the shock are significantly more likely to start new, clean R&D projects, compared to firms that are not exposed. In columns (2) and (3) we show the results from using the “R&D to Clean” dummy. In column (2), all firms are included, regardless of whether or not they report any R&D spending, In column (3), we limit the sample to firms that report positive R&D investments before the shock. We, again, find that firms that are more exposed to the shock are more likely to start new clean R&D projects – this effect is particularly strong if we narrow the sample to include only R&D performers.

Table 4: Switching into Clean R&amp;D

Variable:	“New Clean” (1)	“R&D to Clean” (2)	“R&D to Clean” (3)
$Post_t \times x_{oi}$	0.033*** (0.011)	0.018** (0.009)	0.056*** (0.022)
Controls	Yes	Yes	Yes
Firm FE	Yes	Yes	Yes
Industry*year FE	Yes	Yes	Yes
Control group	All firms	All firms	R&D firms
Observations	11,695	11,695	4,751

Note: Standard errors in parenthesis are clustered on firm. “New Clean” is a dummy that takes the value of 1 if the firm has positive investments in Clean R&D in year  $t$ , but not in  $t-1$ . “R&D to Clean” is the same as “New Clean” conditional on having invested in R&D in  $t-1$ . Controls include baseline levels of log employment, log tangible assets, export share, energy share and a dummy for public funding, all interacted with year dummies.  $*p < 0.1, **p < 0.05, ***p < 0.01$ .

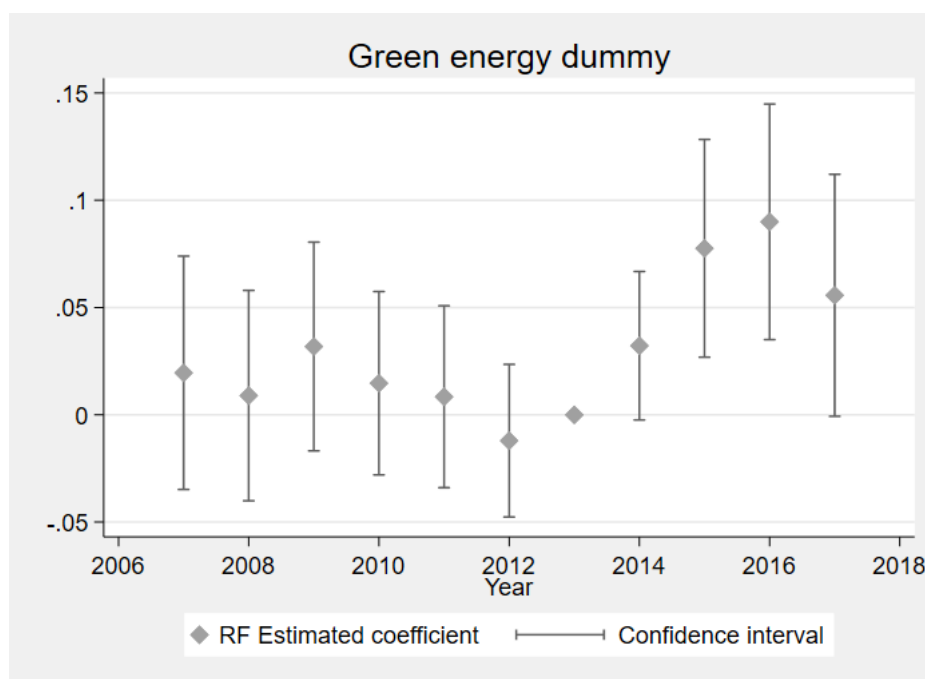

To summarize our results: we find that firms that are more exposed to the 2014 fall in the oil price increase their clean R&D more than firms that were less exposed to the shock. This is true if we look at the likelihood of investing in clean R&D, the share of clean relative to non-clean R&D, or the value of clean R&D. We also document that the firms which are most exposed to the shock have higher probabilities of starting new investments in clean R&D, and switching from non-clean to clean R&D. We will now explore what mechanisms are at play to produce these effects. Clean R&D in more exposed firms reacting more strongly to the oil price shock indicates that within-firm dynamics such as adjustment costs, are relevant for the understanding the full effect of such price drops on green technological progress.

**Robustness** A potential concern is that more exposed firms face different pre-trends compared to those less exposed. Similar pre-trends for the two groups of firms would be reassuring, indicating that our identification strategy is solid. We investigate the pretrends by estimating the dynamic pattern of our main outcome variable, the dummy for clean R&D:

$$y_{kt} = \alpha_k + \beta x_{ok} \times \delta_t + \gamma Z_{kt} + \delta_{st} + \varepsilon_{kt}, \quad (18)$$

The result from estimating this specification is illustrated in Figure 7. First, the lack of evidence of any sort of pattern in the pre-trends is reassuring, and suggests that our treatment and control firms are behaving similarly in our pre-period. We see a clear upward trajectory beginning in 2014 and turning significant from 2015.

Figure 7: Dynamic DID

Note Each point presents the event-study coefficient estimates and 90% confidence intervals of Equation 18.

Although our dynamic difference-in-difference estimation is reassuring, one cannot exclude the possibility that our results are driven by something other than the oil price. In particular, if clean energy prices increased substantially during the time period we are looking at, this would have incentivized firms to ramp up their clean R&D investments., and exposed firms might in theory be hit differently by changes in clean energy prices, compared to less exposed firms. However, figure 9 in Appendix Section D shows how clean energy prices evolved over our sample period. If anything, they declined smoothly over the time period in question.

**Mechanisms** In our theoretical framework, within-firm reallocation from non-clean to clean R&D after a negative oil price shock is driven by the fall in expected profits from producing inputs for the oil-extracting sector. We therefore next investigate whether the firms we identify as being more exposed to the negative oil price shock experience subsequent decreases in sales and profits. We create two new variables, sales per employee and an indicator variable for operating profits. The indicator takes on the value of either 0, -1 or 1, depending on whether the firms makes zero, negative or positive profits. We estimate Equation (17) with these two new variables as dependent variables. The results from these regressions can be found in Table 5. We find that sales per employee decreases significantly, as does profits, although the latter finding is not as robust as the first. Our

results suggest that the mechanism suggested by the theoretical model is indeed at play.

Table 5: Sales per employee and Profits indicator

Variable:	Sales per emp. (1)	Sales per emp. (2)	Profits indicator (3)	Profits indicator (4)
$Post_t \times x_{oi}$	-0.082*** (0.026)	-0.043* (0.026)	-0.179*** (0.049)	-0.081 (0.060)
Controls	Yes	Yes	Yes	Yes
Firm FE	Yes	Yes	Yes	Yes
Year FE	Yes	No	Yes	No
Industry FE	Yes	No	Yes	No
Industry*year FE	No	Yes	No	Yes
Observations	11,695	11,695	11,695	11,695

Standard errors in parenthesis are clustered on firm. Income is measured as operating income and profits as an indicator for operating profits. Controls include baseline levels of log employment, log tangible assets, export share, energy share and a dummy for public funding, all interacted with year dummies. The indicator for operating profits takes on 0, -1 and 1 depending on whether the firms makes zero, negative or positive profits.  $*p < 0.1$ ,  $**p < 0.05$ ,  $***p < 0.01$ .

Finally, we explore whether the most exposed firms simply intensify their R&D investments across the board, relative to other firms. As shown in Table 6, we find no effects on total R&D investments, the number of R&D employees, or on the share of R&D employees in total employment. These results suggest that firms are not scaling up all R&D investments in response to the shock. Rather, in line with our theoretical predictions, they are reallocating resources towards clean R&D investments.

Table 6: R&D

Variable:	R&D dummy (1)	log R&D emp (2)	R&D emp share (3)
$Post_t \times x_{oi}$	-0.015 (0.028)	-0.008 (0.007)	-0.001 (0.001)
Controls	Yes	Yes	Yes
Firm FE	Yes	Yes	Yes
Industry*year FE	Yes	Yes	Yes
Observations	11,695	11,695	11,695

Standard errors in parenthesis are clustered on firm. Log R&D employment is  $\log(1 + \text{R\&D employees})$ . Controls include baseline levels of log employment, log tangible assets, export share, energy share and a dummy for public funding, all interacted with year dummies.  $*p < 0.1$ ,  $**p < 0.05$ ,  $***p < 0.01$ .

## 6 Concluding Remarks

In this paper, we aim to shed light on a potentially important channel through which changes in the price of fossil fuels may affect investments in clean technology. We do so by developing a theoretical framework that highlights the role of within-firm dynamics in adjusting to a price shock. We take the theory to the data, and our empirical findings demonstrate that the long-term impacts of changes in energy prices through this less researched channel might be substantial. Our results indicate that the combination of supply chain effects and within-firm dynamics may be essential in driving the shift in resources from dirty towards clean R&D and technological development.

Our findings have some key policy implications. Understanding the mechanisms through which firms react to external price shocks and the subsequent reallocation of resources is crucial for designing effective policies that promote environmentally sustainable economic growth. We show that policies lowering the profitability in the oil producing sector may promote a shift towards investment in clean R&D, not only through the induced structural change as resources move from fossil towards clean energy producing firms, but also through within-firm reallocation in upstream industries.

# Appendix

## A Data

The R&D survey measures R&D activity in the Norwegian business enterprise sector. The statistics are comparable to statistics for other countries and are reported to the OECD and EUROSTAT. The R&D survey includes: (i) all firms with at least 50 employees; (ii) all firms with less than 50 employees and with reported intramural R&D activity in the previous survey of more than NOK 1 million or extramural R&D of more than NOK 3 million; (iii) among other firms with 10-49 employees a random sample was selected within each strata (NACE 2-digit and size class).

The R&D survey provides details on the share of R&D spend in certain thematic areas. We use information on the share of R&D spent on what we define as clean energy, which encompasses the two areas: Renewable energy and Energy efficiency.

## B Calculations for the analytical model

In the following, we provide the details for calculation of the signs of the first- and second-order effects of the drop in the price of the dirty final good on clean R&D activity, in the analytical model presented in Section 2. The calculations provided in the following makes us able to compare the total effects of the price drop on clean R&D in firms engaged in both clean and dirty R&D (group *III*) relative to firms only engaged in clean R&D (group *I*), and provide proofs for Proposition 1 and 2.

For notational simplicity, let us define the function  $H_{kjt}^l(\cdot)$  as the derivative of the objective function (Equation 12) of firm  $k$ , belonging to group  $l$ , with respect to  $s_{kjt}$ .  $H_{kjt}^l(\cdot)$  represents the net value of a marginal increase in  $s_{kjt}$  for firm  $k$  in group  $l$ . Each firm will hire scientists until the relevant marginal value is zero, i.e. until  $H_{kjt}^l(\cdot) = 0$ .

For firms in group *I* and *II*, the first-order conditions are given by:

$$H_{kct}^I(s_{kct}, p_{ct}, w_t) = \alpha(1 - \alpha)(1 + \gamma)\eta_c A_{ct-1} p_{ct}^{\frac{1}{1-\alpha}} \frac{\partial g^c(s_{kct}, 0)}{\partial s_{kct}} - w_t - 2c \frac{s_{kct} - s_{kct-1}}{s_{kct-1}^2} = 0 \quad (19)$$

$$H_{kdt}^{II}(s_{kdt}, p_{dt}, w_t) = \alpha(1 - \alpha)(1 + \gamma)\eta_d A_{dt-1} p_{dt}^{\frac{1}{1-\alpha}} g^{d'}(s_{kdt}) - w_t - 2c \frac{s_{kdt} - s_{kdt-1}}{s_{kdt-1}^2} = 0. \quad (20)$$

For firms in group *III*, the two first-order conditions are given by:

$$H_{kct}^{III}(s_{kct}, s_{kdt}, p_{ct}, w_t) = \alpha(1 - \alpha)(1 + \gamma)\eta_c A_{ct-1} p_{ct}^{\frac{1}{1-\alpha}} \frac{\partial g^c(s_{kct}, s_{kdt})}{\partial s_{kct}} - w_t - 2c \frac{s_{kt} - s_{kt-1}}{s_{kt-1}^2} = 0 \quad (21)$$

$$H_{kdt}^{III}(s_{kct}, s_{kdt}, p_{ct}, p_{dt}, w_t) = \alpha(1 - \alpha)(1 + \gamma) \left( \eta_c A_{ct-1} p_{ct}^{\frac{1}{1-\alpha}} \frac{\partial g^c(s_{kct}, s_{kdt})}{\partial s_{kdt}} + \eta_d A_{dt-1} p_{dt}^{\frac{1}{1-\alpha}} g^{d'}(s_{kdt}) \right) - w_t - 2c \frac{s_{kt} - s_{kt-1}}{s_{kt-1}^2} = 0 \quad (22)$$

with  $s_{kt} = s_{kct} + s_{kdt}$ .

The first-order conditions in equations 19-22 give the demand for scientists from all three groups of firms.

In the following, the group-specific superscripts are dropped for expressions that take the same value for all relevant groups. For group *I* and *II*, respectively, the following second-order conditions ensure that the first-order conditions characterize a maximum:

$$\frac{\partial H_{kct}}{\partial s_{kct}} = \alpha(1 - \alpha)(1 + \gamma)\eta_c A_{ct-1} p_{ct}^{\frac{1}{1-\alpha}} \frac{\partial^2 g^c}{\partial s_c^2} - \frac{2c}{s_{kt-1}^2} \leq 0 \quad (23)$$

$$\frac{\partial H_{kdt}}{\partial s_{kdt}} = \alpha(1 - \alpha)(1 + \gamma)\eta_d A_{dt-1} p_{dt}^{\frac{1}{1-\alpha}} g^{d''} - \frac{2c}{s_{kt-1}^2} \leq 0. \quad (24)$$

These inequalities follow directly from our initial assumptions. For group *III*, we also require that:

$$\frac{\partial H_{kct}}{\partial s_{kct}} \frac{\partial H_{kdt}}{\partial s_{kdt}} - \left( \frac{\partial H_{kct}^{III}}{\partial s_{kdt}} \right)^2 \geq 0 \quad (25)$$

with

$$\frac{\partial H_{kct}^{III}}{\partial s_{kdt}} = \frac{\partial H_{kdt}^{III}}{\partial s_{kct}} = \alpha(1 - \alpha)(1 + \gamma)\eta_c A_{ct-1} p_{ct}^{\frac{1}{1-\alpha}} \frac{\partial^2 g^c}{\partial s_c \partial s_d} - 2c \frac{1}{s_{kt-1}^2} \leq 0. \quad (26)$$

The cross-derivative of the objective function of a firm in group *III* is positive if the spillover effect dominates the effect of the adjustment cost, while it is negative if the adjustment cost dominates. In either case, we assume that Equation (25) holds, i.e. that the effect of dirty-scientist hiring on the marginal value and cost of hiring scientists for clean innovation, independent of its direction, is not large enough to prevent an interior

solution to the problem of any firm in group *III*.

**First-order effects of the oil price drop.** To get at the effects of the price drop on each firm's R&D activity (demand for scientists), we use the first-order conditions. First, differentiating the first-order conditions with respect to  $p_{dt}$  and  $w$  gives:

$$\frac{\partial H_{kdt}^l}{\partial p_{dt}} = \alpha(1 + \gamma)\eta_d A_{dt-1} p_{dt}^{\frac{-\alpha}{1-\alpha}} g^{d'}(s_{kdt}^l) > 0, \quad \text{for } l = II, III. \quad (27)$$

$$\frac{\partial H_{kjt}^l}{\partial w_t} = -1, \quad \text{for } l = I, II, III \text{ og } j = d, t \quad (28)$$

Next, it follows directly from differentiating the first-order conditions and using the inequalities in equations 23-26 that:

$$\frac{\partial s_{kdt}^{II}}{\partial p_{dt}} = -\frac{\frac{\partial H_{kdt}^{II}}{\partial p_{dt}}}{\frac{\partial H_{kdt}}{\partial s_{kdt}}} > 0 \quad (29)$$

$$\frac{\partial s_{kdt}^{III}}{\partial p_{dt}} = -\frac{\frac{\partial H_{kct}}{\partial s_{kct}} \frac{\partial H_{kdt}^{III}}{\partial p_{dt}}}{\frac{\partial H_{kct}}{\partial s_{kct}} \frac{\partial H_{kdt}}{\partial s_{kdt}} - \left(\frac{\partial H_{kct}^{III}}{\partial s_{kdt}}\right)^2} > 0 \quad (30)$$

$$\frac{\partial s_{kct}^{III}}{\partial p_{dt}} = \frac{\frac{\partial H_{kct}^{III}}{\partial s_{kdt}} \frac{\partial H_{kdt}^{III}}{\partial p_{dt}}}{\frac{\partial H_{kct}}{\partial s_{kct}} \frac{\partial H_{kdt}}{\partial s_{kdt}} - \left(\frac{\partial H_{kct}^{III}}{\partial s_{kdt}}\right)^2} \leq 0 \quad (31)$$

$$\frac{\partial s_{kct}^{III}}{\partial p_{dt}} + \frac{\partial s_{kdt}^{III}}{\partial p_{dt}} = \frac{\alpha(1 - \alpha)(1 + \gamma)\eta_c A_{ct-1} p_{ct}^{\frac{1}{1-\alpha}} \left(\frac{\partial^2 g^c}{\partial s_c \partial s_d} - \frac{\partial^2 g^c}{\partial s_c^2}\right) \frac{\partial H_{kdt}^{III}}{\partial p_{dt}}}{\frac{\partial H_{kct}}{\partial s_{kct}} \frac{\partial H_{kdt}}{\partial s_{kdt}} - \left(\frac{\partial H_{kct}^{III}}{\partial s_{kdt}}\right)^2} > 0 \quad (32)$$

**Effects of wage changes.** Similarly, it follows, again from differentiating the first-order conditions and using 23-26, that:

$$\frac{\partial s_{kct}^I}{\partial w_t} = 1 \left/ \frac{\partial H_{kct}}{\partial s_{kct}} \right. < 0, \quad (33)$$

$$\frac{\partial s_{kdt}^{II}}{\partial w_t} = 1 \left/ \frac{\partial H_{kdt}}{\partial s_{kdt}} \right. < 0, \quad (34)$$

$$\frac{\partial s_{kct}^{III}}{\partial w_t} = \left(-\frac{\partial H_{kct}}{\partial s_{kdt}} + \frac{\partial H_{kdt}}{\partial s_{kdt}}\right) \left/ \left(\frac{\partial H_{kct}}{\partial s_{kct}} \frac{\partial H_{kdt}}{\partial s_{kdt}} - \left(\frac{\partial H_{kct}^{III}}{\partial s_{kdt}}\right)^2\right) \right. < 0 \quad (35)$$

$$\frac{\partial s_{kdt}^{III}}{\partial w_t} = \left(-\frac{\partial H_{kct}}{\partial s_{kdt}} + \frac{\partial H_{kct}}{\partial s_{kct}}\right) \left/ \left(\frac{\partial H_{kct}}{\partial s_{kct}} \frac{\partial H_{kdt}}{\partial s_{kdt}} - \left(\frac{\partial H_{kct}^{III}}{\partial s_{kdt}}\right)^2\right) \right. < 0. \quad (36)$$

The market equilibrium condition in Equation 13 gives the equilibrium wage as a

function of final good prices:  $w_t(p_{ct}, p_{dt})$ . Differentiating shows that the wage will drop as a consequence of a fall in the fossil energy price:

$$\frac{\partial w_t}{\partial p_{dt}} = - \frac{\lambda^{II} \frac{\partial s_{kdt}^{II}}{\partial p_{dt}} + \lambda^{III} \left( \frac{\partial s_{kct}^{III}}{\partial p_{dt}} + \frac{\partial s_{kdt}^{III}}{\partial p_{dt}} \right)}{\lambda^I \frac{\partial s_{kct}^I}{\partial w_t} + \lambda^{II} \frac{\partial s_{kdt}^{II}}{\partial w_t} + \lambda^{III} \left( \frac{\partial s_{kct}^{III}}{\partial w_t} + \frac{\partial s_{kdt}^{III}}{\partial w_t} \right)} > 0. \quad (37)$$

We can now turn to the proof of Proposition 1 and 2.

**Proof of Proposition 1 and 2.** Define

$$\Delta \equiv - \frac{ds_{kct}^{III}}{dp_{dt}} - \left( - \frac{ds_{kct}^I}{dp_{dt}} \right), \quad (38)$$

with

$$\frac{ds_{kct}^{III}}{dp_{dt}} = \frac{\partial s_{kct}^{III}}{\partial p_{dt}} + \frac{\partial s_{kct}^{III}}{\partial w_t} \frac{\partial w_t}{\partial p_{dt}} \quad (39)$$

$$\frac{ds_{kct}^I}{dp_{dt}} = \frac{\partial s_{kct}^I}{\partial w_t} \frac{\partial w_t}{\partial p_{dt}} \quad (40)$$

Insert from Equation (??) and (37) and reorganize, to get:

$$\Delta = \lambda^I X_1 + \lambda^{II} X_2 + \lambda^{III} X_3, \quad (41)$$

with:

$$X_1 = \frac{\partial s_{kct}^{III}}{\partial p_{dt}} \frac{\partial s_{kct}^I}{\partial w_t} \begin{cases} > 0 \text{ if } \frac{\partial s_{kct}^{III}}{\partial p_{dt}} < 0 \\ < 0 \text{ if } \frac{\partial s_{kct}^{III}}{\partial p_{dt}} > 0 \end{cases} \quad (42)$$

$$X_2 = \frac{\frac{\partial H_{kdt}^{II}}{\partial p_{dt}}}{\frac{\partial H_{kct}}{\partial s_{kct}} \frac{\partial H_{kdt}}{\partial s_{kdt}} - \left( \frac{\partial H_{kct}^{III}}{\partial s_{kdt}} \right)^2} \frac{\frac{\partial H_{kct}^{III}}{\partial s_{kdt}}}{\frac{\partial H_{kct}}{\partial s_{kct}} \frac{\partial H_{kdt}}{\partial s_{kdt}}} \left( \frac{\partial H_{kct}^{III}}{\partial s_{kdt}} - \frac{\partial H_{kct}^{III}}{\partial s_{kct}} \left( 1 - \frac{g^{dI}(s_{kdt}^{III})}{g^{dI}(s_{kdt}^I)} \right) \right), \quad (43)$$

$$X_3 = \frac{\frac{\partial H_{kdt}^{III}}{\partial p_{dt}}}{\frac{\partial H_{kct}}{\partial s_{kct}} \frac{\partial H_{kdt}}{\partial s_{kdt}} - \left( \frac{\partial H_{kct}^{III}}{\partial s_{kdt}} \right)^2} \frac{\frac{\partial H_{kct}^{III}}{\partial s_{kdt}}}{\frac{\partial H_{kct}}{\partial s_{kct}}} \begin{cases} > 0 \text{ if } \frac{\partial s_{kct}^{III}}{\partial p_{dt}} < 0 \\ < 0 \text{ if } \frac{\partial s_{kct}^{III}}{\partial p_{dt}} > 0 \end{cases} \quad (44)$$

The first fraction in  $X_2$  is always non-negative. The second fraction takes the same sign as the fraction  $\partial H_{kct}^{III}/\partial s_{kdt}$ , positive if the spillover effect dominates, negative if the adjustment cost effect dominates. Next, the expression inside the inner brackets will take a negative value as long as  $s_{kdt}^{III} \leq s_{kdt}^{II}$ . With  $s_{kt-1}^{III} = s_{kt-1}^{II}$ , where the group-*III* firm uses only a share of their scientists for dirty R&D, we assume in the following that this is the case. The second term in the outer brackets will then take a positive value.

If the adjustment costs dominates, the full expression in the outer brackets will be negative, and  $X_2$  will take the opposite value of  $\partial H_{kct}^{III}/\partial s_{kdt}$ . The same will be the case if the spillover effect dominates, as long as  $\partial H_{kct}^{III}/\partial s_{kdt}$  is not large too large. In the main body of the paper, we assume this is the case. However, it is worth noting that for the special case of very large spillover effects,  $X_2$  may take the same sign as  $\partial H_{kct}^{III}/\partial s_{kdt}$ . As a consequence, if  $\lambda^{II}$  is sufficiently large, the same can become true for the full expression for  $\Delta$  in Equation (38). The firms in group *II* will react to the price drop by decreasing their demand for scientists, which will push the wage down. If the share of firms belonging to this group is very large, the firms in group *III* may face a wage drop that is large relative to the drop in prices.

Given the signs of  $X_1, X_2$  and  $X_3$ , disregarding the special case just described, we have:

$$\Delta \begin{cases} > 0 \text{ if } \frac{\partial s_{kct}^{III}}{\partial p_{dt}} < 0 \\ = 0 \text{ if } \frac{\partial s_{kct}^{III}}{\partial p_{dt}} = 0 \\ < 0 \text{ if } \frac{\partial s_{kct}^{III}}{\partial p_{dt}} > 0 \end{cases}$$

i.e., exposed-firm clean R&D increase more than clean R&D in non-exposed firms if the rescaling cost dominates, while one would see the largest increase in the non-exposed firms (and possibly even a decrease in exposed firms) if the spillover effect dominates. This concludes the proof.

Note that the analysis presented above assumes interior solution to the maximization problem of the firms with respect to  $s_{kjt}$  in for all firms with  $\eta_{kjt} = \eta_j$ . As a consequence, a drop in the dirty-good price will only induce intensive-margin shifts in clean R&D, as all firms with the ability to engage in clean R&D will have  $s_{kct} > 0$  for any set of prices, by assumption. However, allowing the marginal productivity of innovation to be finite as  $s_{kct}$  approaches 0:  $\lim_{s_{kct} \rightarrow 0} g^c(s_{kct}, s_{kdt}) \neq \infty$ , would induce firms in group *I* and *III* to engage in clean R&D activity only if the expected revenue is sufficiently high. As a result, a drop in the dirty-good price would potentially induce increases in clean R&D in both groups both on the extensive and on the intensive margin.

## C The firm-level measure of exposure to the oil price drop

We use a two-step process to identify the level of exposure of each firm in our dataset to the 2014 oil price drop.

First, we categorize all products imported to Norway as oil related or not oil related. In this first step, we rely on data on imports to oil producing firms in Norway. All products that are imported by these firms are defined as oil related. In the period before the 2014 oil price drop, around 7000 products are imported to Norway, and about 1800 of these are imported (in any quantity) by the oil producing sector, and thereby defined as oil related in our measure.

When determining which products to define as inputs to the oil production, we take into account the potentially strong home bias of the oil extraction sector operating in Norway regarding the sourcing of inputs. Since the start of Norwegian oil extraction, it has been a stated goal to build a Norwegian supply sector, and strong policy measures have been in place to obtain this goal.

Building on Armington (1969) we assume that the production function of the oil producers encompass different preferences for domestically produced and foreign inputs :

$$Y_{dt} = \beta_{di} \int_0^1 A_{Ddit}^{1-\alpha} x_{Ddit}^\alpha di + (1 - \beta_{di}) \int_0^1 A_{Mdit}^{1-\alpha} x_{Mdit}^\alpha di, \quad (45)$$

with subscript  $D$  denoting domestically produced inputs and subscript  $M$  denoting foreign inputs, while  $\beta_{di}$  is the value of the imported good in production relative to the domestically produced good. The size of  $\beta_{di}$  determines the home bias for input  $di$ . For higher values of  $\beta_{di}$ , input demand would be directed more towards domestically produced goods. If the home bias differs across sectors and inputs, the share of imports of good  $x_{di}$  that is directed towards the oil producing sector will not be informative of the relative importance of good  $x_{di}$  as an input in the oil producing sector. Therefore, we do not weight the goods categorized as inputs to the oil producing sector using import shares.

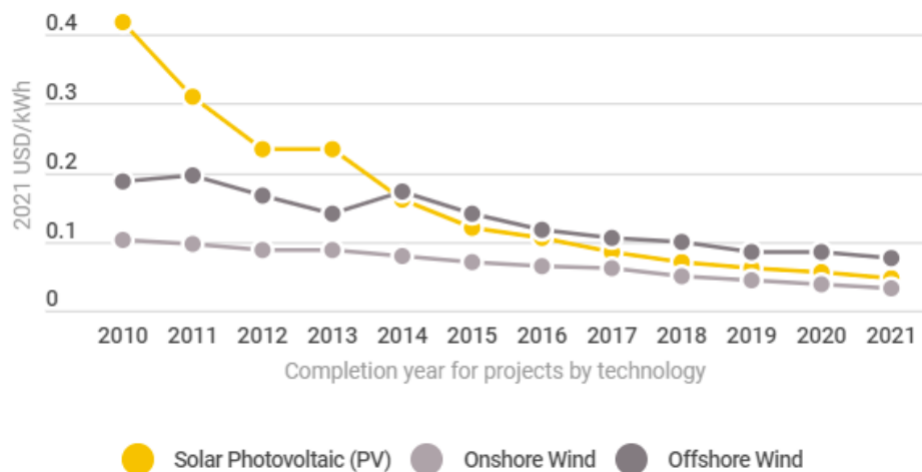

## D Additional Figures

Figure 8: Producer Price Index - Norway (2021=100)

The figure shows the development of the producer price index for the domestic market for the commodities/industries (i) oil- and gas extraction, (ii) electricity, gas and steam and (iii) the aggregate of energy goods with 2021 as the reference year (2021=100).

Figure 9: Global renewable costs (IRENA)

The figure shows the development of cost of renewable energy according to technology. Source: IRENA ([www.irena.org](http://www.irena.org))
